STA240 Final Project

Anthony Zhao, Abby Li, William Yan

Scenario 1

Customer Arrival

Poisson process (rate = λ)

- T_k : Arrival time of the kth customer
- W_k : Time between the k-1th arrival and the kth arrival

$$W_k = T_k - T_{k-1}.$$

 $W_k \sim Pois(\lambda)$

where $\lambda = 5$ customers per hour

Service Time

$$S_k \sim Exp(\lambda)$$

where $\lambda=6$ customers per hour, so the average customer needs to wait 1/6 hours = 10 minutes.

Arrival Times

```
library(tidyverse)
library(lubridate)
set.seed(121)
# simulating the arrival times of customers throughout the day
# Poisson process (lambda = 5)
# Tk= arrival time of the kth customer
# Wk= time between the k-1th customer arrival and the kth customer arrival where Wk \sim Pois(1
# set parameter
lambdaA <- 5 # in units: customers per hour</pre>

Arrival Times Analysis

In this simulation, the number of customers that will be arriving within the operating hours is 60, with the first customer arriving 15 minutes after opening and the last customer arriving 67 minutes before closing

Serving Times

```
# given the output from above, simulate the serving times of customers before they leave
# notice that service time is modeled by exp(6)
lambdaS <- 6 # customers per hour
lambdaS <- lambdaS/60 # customers per minute
# simulate customer's service time
# n= only simulating the service time for those where T_sample <= total_time
service_times <- rexp(length(arrival_times), rate= lambdaS)
#these are the serving times for each arriving customer before they leave
service_times</pre>
```

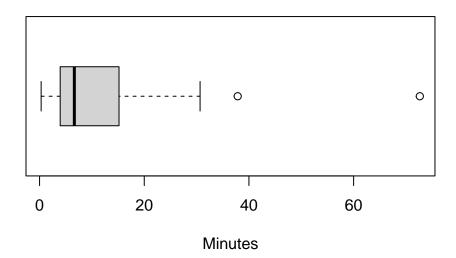

```

Serving Times Analysis

```
boxplot(service_times, horizontal= TRUE, main= "Service Times", xlab= "Minutes")
```

Service Times

The average service time is 11 minutes, with the data skewed right, consistent with an exponential distribution. This indicates that service times tend to lower.

Time of the day with arrival time

```
# Start time as POSIXct
start_time <- as.POSIXct("10:00", format = "%H:%M", tz = "UTC")
# Add minutes to the start time</pre>
```

```
time_of_day <- sapply(arrival_times, function(m) {
    m <- round(m)  # Round to nearest whole number
    new_time <- start_time + (m * 60)  # Add minutes converted to seconds
    format(new_time, "%H:%M")  # Format as "HH:MM"
})

print(time_of_day)

```

Scenario 2

Arrival and Service

Assumptions:

- $1.\,\,5$ dining tables and L chefs with operating hours $10\mathrm{am}$ $10\mathrm{pm}$
- 2. each table only seats one customer
- 3. service time modeled by an exponential distribution with rate S = 3L, so that the more chefs there are, the faster the service times become (this is not very realistic)

```
# first, we generate the arrival times similar in scenario 1
lambdaA <- 24 # per hour
opening_time <- hm("10:00")
closing_time <- hm("22:00")
hours <- hour(closing_time) - hour(opening_time)
total_time <- hours*60 # operating hours in minutes
lambdaA <- lambdaA/60 # per minute

n <- ceiling(lambdaA*total_time) # max number of customers
W_sample <- rexp(n, rate= lambdaA)</pre>
```

```
T_sample <- numeric(n)

for(i in 1:n) {
    T_sample[i] <- sum(W_sample[1:i])
}

arrival_times <- T_sample[T_sample <= total_time]

# next, we generate the service times similar to scenario 1

# make a function to do this
calc_service_times <- function(arrivals, chefs) {
    # Ensure rate is per unit time
    minute_rate = (3*chefs) / 60
    services = rexp(length(arrivals), rate = minute_rate)
    return(services) # in minutes
}

# if we only have one chef
service_times <- calc_service_times(arrivals = arrival_times, chefs = 2)</pre>
```

Waiting Times

To model waiting times, we iterate through the day minute by minute.

```
tables <- 5
arrival_times_temp <- arrival_times

# number of people in line each minute
queue_size_history <- numeric(total_time)

# number of tables occupied each minute
occupied_tables_history <- rep(0, total_time)

# timer to track remaining waiting time for each table in the restaurant
# each element is one table in the restaurant
# -1 means empty
# otherwise, number of remaining service minutes
tables_timer <- rep(-1, tables)

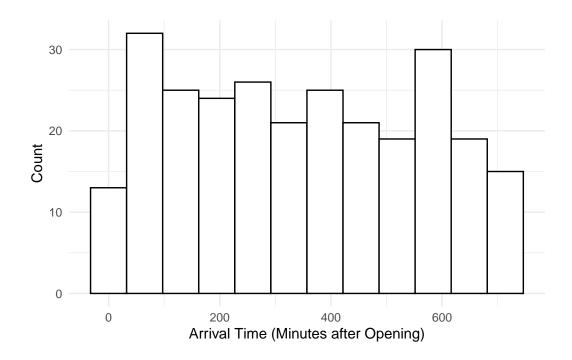

# the amount of minutes each customer of that day waited
waiting_times <- numeric(0)</pre>
```

```
# the arrival_times indices of the people currently in line
# in order to know how long their eventual service time will be
queue <- numeric(0)
# an internal counter separate from the time
customers_entered <- 0

Restaurant Profits

Assumptions:

- 1. each customer spends \$50 per meal (customers who are still in the queue when the restaurant closes won't pay)
- 2. each chef earns a wage of \$40 per hour (paid for the entire duration of the restaurant's operating hours)

Maximizing Profits

Should we run this simulation multiple times to create a PDF of the total daily profits? How many chefs should we hire?

Down-time of Restaurant

How does the occupancy of the restaurant vary throughout the day? Does that inform any of our recommendations?
